Chapter 1

Introduction

Science case

Galaxy Clusters

IMF

DM fraction in comparison with the IMF

Studying the matter distribution given by strong gravitational lensing can give us information about the IMF of the BCGs

Old stuff

mass to light ratio of 4

percentage of dark matter will allow me to define the IMF more precisely. I want to see what fraction of the mass, what fraction of the surface density is stars

make a plot of the mass as a function of the radius of the cluster

strong lensing at different radii is useful.

if I got to certain radius I will have more dark matter, because light drops quickly.

given my science case, am I maybe too pessimistic? should I look inside the Einstein radius? we want to know what radius we should be looking at, for that we can make a plot for a cluster with typical parameters,

basically find how much dark matter and how many stars are there in the profile

first step, find the luminosity of the cluster

let's take the case of ABELL1068, it's magnitude in U is 21.94, in I is 18.46, in g is 20.09, in r is 19.5

the distance to the galaxy is 591.42857 Mpc

but using the aparent magnitude and the distance, we get $L=2.9631e+9$

from the NASA webpage: $1.41e+45$

salpeter mass function is $n(M) \propto M^{-2.3}$

the NFW density profile is

$$\rho(r) = \frac{\delta_c \rho_c}{(r/r_s)(1 + r/r_s)^2} \quad (1.1)$$

where the characteristic overdensity is:

$$\delta_c = \frac{200}{3} \frac{c^3}{\ln(1+c) - c/(1+c)} \quad (1.2)$$

from Munoz cuartas et. al. we see that the concentration parameter depends on the mass and the redshift as we see in the following plot:

(grafica de Juank)

then the concentration parameter for ABELL1068 is about 4.46

so from the critical density:

$$\rho_c = \frac{3H^2(z)}{8\pi G} \quad (1.3)$$

the critical desntiy would be: $2e-26$ in SI units so in $M_{\text{sol}}/\text{pc}^3$ it is 2.9×10^{-7}

$$H(z) = H_0(1 + \Omega z)^{3/2}$$

the hubble parameter at $z=0.138$ is $H(z)=85.6$

let's take a value of 40 kpc for the concentration parameter given by $r_s = r_{200}/c$

delta c is 6716.38

2.1 Galaxy Clusters

Glas.

dwarf stars contribute very little to the integrated light from an old stellar population (Smith 2015)

Galaxy clusters contain a population of stars gravitationally unbound to individual galaxies, yet still bound to the clusters overall gravitational potential, created by the stripping of stars from galaxies during interactions and mergers

FIGURE 2.1: G

The image of galaxy cluster MACS J1206.2-0847 (or MACS 1206) is part of a broad survey with NASA Hubble Space Telescope. The distorted shapes in the cluster are distant galaxies from which the light is bent by the gravitational pull of an invisible material called dark matter within the cluster of galaxies. This cluster is an early target in a survey that will allow astronomers to construct the most detailed dark matter maps of more galaxy clusters than ever before. These maps are being used to test previous, but surprising, results that suggest that dark matter is more densely packed inside clusters than some models predict. This might mean that galaxy cluster assembly began earlier than commonly thought.

Scientists are planning to observe a total of 25 galaxy clusters under a project called CLASH (Cluster Lensing and Supernova survey with Hubble). One of the first objects observed for the new census is the galaxy cluster MACS J1206.2-0847. This conglomeration of galaxies is one of the most massive structures in the universe, and its gigantic gravitational pull causes stunning gravitational lensing. MACS 1206 lies 4 billion light-years from Earth. In addition to curving of light, gravitational lensing often produces double images of the same galaxy. In the new observation of cluster MACS J1206.2-0847, astronomers counted 47 multiple images of 12 newly identified galaxies. The era when the first clusters formed is not precisely known, but is estimated to be at least 9

billion years ago and possibly as far back as 12 billion years ago. If most of the clusters in the CLASH survey are found to have excessively high accumulations of dark matter in their central cores, then it may yield new clues to the early stages in the origin of structure in the universe.

$$I(R)\sigma_p^2(R) = \frac{2}{\Gamma} \int_R^\infty \left(1 - \beta \frac{R^2}{r^2}\right) \frac{\nu \bar{v}_r^2 r dr}{\sqrt{r^2 - R^2}} \quad (2.1)$$

Whuster.

2.2 Gravitational Lensing

At small radii, stars dominate the lensing mass, so that lensing provides a direct probe of the stellar mass to light ratio, with only small corrections needed for dark matter.

In the paper of Russell Smith (a giant elliptical galaxy with a lightweight initial mass function) they find a stellar mass to light ratio of 3.01 plus minus 0.25

Modelling the lensing configuration provides the total projection mass within an aperture.

bulges have heavier IMFs than disks

Several recent studies have presented evidence for "heavyweight" IMFs in giant ellipticals, with a mass-to-light-ratio twice that of a Milky Way like IMF.

NFW profile for dark matter that is basically the dynamical mass of the cluster

2.3 IMF in BCGs

Chapter 3

Observational Procedures

the full description of the survey is in: D. J. Sand et. al. 2011

MegaCam wide field imager on the CFHT (Canada-France-Hawaii Telescope). The cluster sample consisted of 101 clusters within the range of redshifts from $0.05 < z < 0.55$

58 clusters from the MENEACs (Multi-Epoch nearby cluster survey)

The meneacs clusters represent all clusters in the BAX X-ray cluster database that are observable for the CFHT

the redshifts of the clusters as given by C. Bildfell et. al. 2012
